

1 **ABSTRACT**

2 A stateless distributed computer architecture allows state-caching objects,  
3 which hold server state information, to be maintained on a client or network rather  
4 than on a server. In one implementation, the computer architecture implements  
5 object-oriented program modules according to a distributed component object  
6 model (DCOM). Using an object-oriented network protocol (e.g., remote  
7 procedure call), a client-side application calls through an application program  
8 interface (API) to a program object residing at a server computer. The program  
9 object, responsive to the call, creates a state caching object that contains state  
10 information pertaining to the client connection. The server inserts the state-  
11 caching object into a local thread context and processes the request to generate a  
12 reply. The server subsequently attaches the state-caching object to the reply and  
13 returns them both to the client. The client stores the state-caching object for later  
14 communication with the server. When the client subsequently calls the program  
15 object at the server, the client submits the state-caching object along with the  
16 request packet. The server uses the state information in the state-caching object to  
17 quickly restore state for the client reconnection. In this manner, the server can  
18 offload its state information to other computing devices in the distributed  
19 architecture, thereby improving scalability. In another implementation, the  
20 network itself caches the server-oriented state-caching object.
